THE AUSTRALIAN ANTS OF THE GENUS
PRISTOMYRMEX, WITH A CASE OF APPARENT
CHARACTER DISPLACEMENT¹

BY ROBERT W. TAYLOR
Biological Laboratories, Harvard University

INTRODUCTION

The Old World myrmicine ant genus, Pristomyrmex Mayr 1866, contains about 40 named forms, mostly from rain forests of the Ethiopian, Oriental and Australian regions. The Australian mainland fauna is small compared to that of New Guinea; it includes four species, three of which are newly described here. There are two species-groups, those of *P. foveolatus* n. sp., and *P. quadridentatus* (André) 1905, each containing two species.

The former group includes *P. foveolatus* and *P. thoracicus* n. sp., closely related species with strong foveolate-reticulate sculpturation, having clear affinities with components of the New Guinean fauna, and known only from rain forests in the Cairns district of North Queensland. *Foveolatus* seems to be restricted to the Atherton Tableland, at elevations greater than 1000 ft, while *thoracicus* is apparently more widespread, but is not known from the Tableland proper.

The affinities of the *quadridentatus* group are less clear; its species occur further south, in extreme S.E. Queensland, and N.E. New South Wales, and they may be derived from a separate, older, Melanesian stock. The group includes *P. quadridentatus* and *P. wheeleri* n. sp. *Quadridentatus* was originally placed in a separate monotypic genus, Odontomyrmex André 1905, which was synonymized with *Pristomyrmex* by Emery (1922). The lack of foveolate sculpturation on the head and body, and the presence of pronotal spines were thought by André to taxonomically characterize *Odontomyrmex*. But these characters occur together or separately in many *Pristomyrmex* species, and cannot be used to logically define a separate taxon (Brown, 1953). Nonetheless the "*Odontomyrmex"" habitus seems to characterize a natural phylectic group within the Australian fauna, and *quadridentatus* and *wheeleri* are undoubtedly cognate, or at least closely related. The former species is typically self-colored golden-brown, but it has an apparently conspecific bicolored variant, *quadridentatus* variety

¹Research supported by U.S. National Science Foundation Grant No. GB 1634 (1963-1965). Australian field studies in 1962, reported here, were supported by the Committee on Evolutionary Biology, Harvard University.
queenslandensis Forel 1915, which is synonymized below. These two forms differ only slightly, except in coloration, and distributional evidence suggests that the bicolored form is a character-displaced variant, produced wherever the range of quadridentatus overlaps that of wheeleri (see fig. 15, plate 3, and discussion on p. 53). Like their northern congener the quadridentatus-group species are known only from rain forest, usually at elevations of +1000 ft.

Available biological information is given in the taxonomic section to follow. Nesting apparently occurs in rotting logs in all species except wheeleri, colonies of which are usually located in the soil, under stones. Feeding and foraging behavior have not been extensively studied, but the bicolored form of quadridentatus forages nocturnally, in the open, on logs, tree trunks and low foliage. It appears that wheeleri may restrict its foraging activity to the soil and leaf litter, since strays have not been taken elsewhere, in spite of extensive search by the author.

All Australian Pristomyrmex types are workers, and the females are known for all species except foveolatus; I have seen no male specimens. Larvae of a North Queensland species were described by G. C. and J. Wheeler (1954). I have been unable to locate adults from the series involved; they would conform to the foveolatus-group diagnosis according to their collector, Dr. W. L. Brown, Jr.

This study is based on material from the Museum of Comparative Zoology collection at Harvard University, from Entomology Division, CSIRO, Canberra, The National Museum of Victoria, Melbourne, and the collection of Rev. B. B. Lowery, S.J., Sydney.

**MEASUREMENTS AND INDICES**

The following abbreviations are used in the descriptions below. Measurements were prepared using a stereomicroscope fitted with an eyepiece scale, reading directly in units of 0.1 and 0.01 mm at 100 × magnification. The measurements cited are the maxima obtained after a series of trials, a fact of special importance when dealing with HL and WL.

**HL** Maximum head length, frontal view, from apex of median clypeal denticle to median occipital border.

**HW** Head width, frontal view, including the eyes.

**CI** Cephalic index (HW × 100)/HL

**SL** Scape length, excluding articular boss and condyle (but including the expanded lamella at base of shaft).

**SI** Scape index (SL × 100)/HW

**PW** Pronotum width, anterior view, immediately below the bases of the pronotal spines.
Scutum Width (females only), dorsal view, across the widest part of the sclerite.

WL Weber’s length of mesosoma, lateral view; in worker, maximum diagonal distance from junction of anterior and dorsal faces of pronotum to apex of inferior metapleural lobe; in female, the anterior limit of measurement is the point where the pro-mesosternal suture meets the anterodorsal mesosomal profile.

Pronotal Spine L(enght), as seen in PW measuring position, true vertical distance between base of spine on its mesial side, and the level of its apex.

Propodeal Spine L(enght), lateral view, maximum distance from apex of spine to opposite edge of propodeal spiracle.

Petiole L(enght), lateral view, from tip of metapleural spine to posterodorsal edge of petiolar tergite.

Postpetiole Height, lateral view, maximum distance from apex of subpostpetiolar process to postpetiolar dorsum.

Eye Diameter, maximum diameter of eye.

Ocular Index (Eye Diameter × 100)/HW.

KEY TO THE AUSTRALIAN PRISTOMYRMEX SPECIES

(Based on the workers)

1. Front of head, between the antennal scrobes, with numerous large shallow umbilicate foveae, their average diameter about 0.05-0.06 mm (group of P. foveolatus) ......................................................... 2

Area of frons between antennal scrobes entirely smooth, lacking sculpture apart from a few minute, pilosity-bearing punctures (group of P. quadridentatus) ......................................................... 3

2. Scapes barely reaching level of occipital border when at rest in the antennal scrobes, with the head held in full-face view (fig. 1); Scape Index 78-83 ......................................................... P. foveolatus n. sp.

Scapes exceeding level of occipital border by 1-1.5 × their maximum thickness when at rest in the antennal scrobes, with the head viewed full-face (fig. 3), Scape Index 96-101 ......................................................... P. thoracicus n. sp.

3. Head relatively narrow (Cephalic Index 97-103) (fig. 7), either concolorous with mesosoma or much lighter in color (plate 3); pronotal spines, in side view, distinctly longer and stronger than those of propodeum (fig. 8) ............................ P. quadridentatus (André)

Head relatively much broader (Cephalic Index 110-116) (fig. 11) and usually much darker in color than the mesosoma (plate 3); pronotal spines subequal in size to propodeal ones, or very slightly smaller (fig. 12) ................................. P. wheeleri n. sp.
Species-level Taxonomy

1. Pristomyrmex foveolatus new species
   (Figs. 1, 2)

   Holotype worker. HL 0.84 mm; HW 0.92 mm; CI 110; SL 0.75
   mm; SI 81; PW 0.55 mm; WL 0.79 mm; Propodeal Spine L 0.35
   mm; Petiole L 0.30 mm; Postpetiole Height 0.30 mm. General
   features as in figures 1 and 2. Mandibles with two adjacent strong
   acute apical teeth and a truncated basal one, separated by a broad,
   shallowly concave diastema. Clypeus with a median longitudinal
   carina, its anterior border with 5 obtuse denticles, the median and
   outer lateral ones largest. Antennal scrobes shallow, their ventral
   borders obscure. Occipital area of cranium enclosed dorsally and
   laterally by a fine arched carina. Scapes barely attaining level of
   occipital border when lying in the antennal scrobes, with the head
   viewed in HL measuring position (see p. 36). Funiculus with a
   3-segmented club, proportions of its segments as in Figure 1. Eyes
   moderately large, maximum diameter 0.12 mm, their anterior edges
   almost twice this distance from the anterior genal borders. Mesosomal
   profile as in Figure 2. Pronotum truncated anteriorly, its inferior
   angles edentate. Humeri each with a small acute tooth about 0.05
   mm long, inclined dorsolaterally to project beyond the main lateral
   outline of the pronotum, when viewed from above. Posterolateral
   corners of pronotal dorsum forming blunt angles of about 90 degrees
   in dorsal view. Anterodorsal edge of mesepisternum extended anteriorly
   as a strong, moderately acute process which partially overlaps the
   fore-coxa. Propodeal spines long, almost straight, each diverging from
   the dorsal midline at an angle of about 20 degrees. Metapleural spines
   small, moderately acute, each about 0.07 mm long, slightly wider at
   base. Petiolar and postpetiolar profiles as in Figure 2. Petiole slightly
   narrower than postpetiole when viewed from above, its crest transverse
   in posterior view and feebly convex.

   Mandibles generally smooth, with several longitudinal ribs.
   Clypeus strongly shining. Head polished and reflective, with numer-
   ous large shallow subcircular umbilicate foveae, averaging about
   0.06 mm in diameter, largest on the posterior genal surfaces, lacking
   on a small smooth area between eye and antennal socket on each side,
   generally separated by distances averaging about one-third their mean
   diameter. Postgenae obscurely foveolate. Antennal scrobes smooth,
   with an almost effaced rugulosity and several arched transverse striae
   anteriorly. Pronotal dorsum obscurely foveolate, with several median
   longitudinal costulae. Posteriorly these meet a transverse carina which
   apparently represents the mesonotum. Propodeal dorsum smooth,
framed by lateral and posterior carinae. Sides of mesosoma generally smooth, ventral parts of mesepisternum, metepisternal area, and sides of propodeum obscurely roughened. Petiole, postpetiole and gaster, antennae and legs, smooth and shining.

Pilosity moderately long and abundant on head and mesosoma, erect to sub-erect, longest on clypeus, crown of head, and pronotal dorsum; shorter erect hairs on scape, sub-erect ones on mandibles, funicular and legs. Hairs lacking on sides of mesosoma. Petiolar and postpetiolar tergites each with three bilaterally symmetrical pairs of hairs (positions as in Figure 2), postpetiolar sternite with a single pair. Gaster very finely pilose apically, its first tergite completely bare. Pubescence lacking.

Color rich golden sienna-brown, mandibles, clypeus, antennae and legs lighter, eyes black, pilosity whitish.

_Type-locality._ Clump Point, west of Tully, N. Queensland.

The holotype was taken in a rotting wood fragment on the floor of very disturbed, depauperate rain forest, a few feet above sea level (June 25, 1962; R. W. Taylor acc. 1746).

_Paratype workers._ Three specimens collected with the holotype resemble it closely; they have the following dimensions: HL 0.82-0.88 mm; HW 0.87-0.96 mm; CI 106-109; SL 0.72-0.75 mm; SI 78-83; PW 0.52-0.57 mm; WL 0.77-0.79 mm; Propodeal Spine L 0.32-0.35 mm; Petiole L 0.29-0.33 mm; Postpetiole Height 0.28-0.30 mm.

An additional specimen from rain forest at Thornton Peak (Mt. Alexander), north-west of Daintree, N. Queensland (elevation not specified but probably +1000 ft (Darlington, 1960: 117), December 20-23, 1957; P. F. Darlington) has: HL 0.85 mm; HW 0.95 mm; CI 112; SL 0.75 mm; SI 79; PW 0.53 mm; WL 0.78 mm; Propodeal Spine L 0.32 mm; Petiole L 0.28 mm; Postpetiole Height 0.29 mm.

This species may show slight unimodal polymorphism. In the short series available SL, and the mesosomal dimensions PW and WL are negatively allometric relative to HW, while HL is positively allometric.

_Distribution and Material Examined._ Known only from the five workers listed above. Clump Point and Thornton Peak are within the area of the main "base-of-peninsula" rain forest system of North Queensland.

_Type deposition._ Holotype and three paratypes in Museum of Comparative Zoology (MCZ) at Harvard University (Type No.
Figures 1-6: North Queensland species of Pristomyrmex foveolatus species-group — *P. foveolatus* n. sp., holotype worker: fig. 1, head, frontal view; fig. 2, mesosoma, petiole and postpetiole, lateral view. — *P. thoracicus* n. sp., holotype worker: fig. 3, head, frontal view; fig. 4, mesosoma, petiole and postpetiole, lateral view. Paratype female: fig. 5, head, frontal view; fig. 6, mesosoma, petiole and postpetiole, lateral view.
31152); one paratype (from Clump Point) in Australian National Insect Collection (CSIRO), Canberra.

2. *Pristomyrmex thoracicus* new species
   (Figs. 3-6)

*Worker.* The following description is based on the holotype and 14 paratypes collected with it. Dimensions (holotype cited first):

- HL 0.95, 0.89-0.96 mm; HW 0.95, 0.89-0.99 mm; CI 100, 98-104;
- SL 0.93, 0.90-0.96 mm; SI 98, 96-101; PW 0.49, 0.45-0.51 mm;
- WL 0.91, 0.87-0.94 mm; Propodeal Spine L 0.30, 0.28-0.32 mm;
- Petiole L 0.34, 0.33-0.36 mm; Postpetiole Height 0.32, 0.28-0.32 mm.

General features as in Figures 3 and 4. Similar to *P. foveolatus*, differentiated from it by the following characters:

1. Relatively narrow head (CI 98-105 against 106-110 in *foveolatus*).

2. Much longer scapes, which surpass the level of the occipital border by 1-1.5 × their maximum thickness when lying in the antennal scrobes, with the head viewed in the HL measuring position (SI 96-101 against 78-83).

3. Proportionately much longer mesosoma (WL 0.94-1.00 × HW, against 0.81-0.89 × in *foveolatus*), which is relatively very narrow (PW 0.51-0.53 × HW, and 0.50-0.55 × WL against 0.56-0.62 × and 0.67-0.73 × respectively in *foveolatus*).

4. Eyes relatively slightly smaller; antennal scrobes more distinctly outlined. Humeral teeth more erect, failing to project beyond lateral pronotal outline when viewed from above. Posterolateral corners of pronotal dorsum obtuse, broadly rounded in dorsal view. Propodeal spines slightly sinuate, their apices turned upwards; diverging from the dorsal midline at angles of about 20 degrees. Metapleural spines more acute. Petiolar crest strongly convex in dorsal view, its outline almost a half circle.

5. Sculpturation virtually identical. Cephalic foveae a little more spaced; sides of mesosoma less sculptured, generally smooth and shining.

6. Pilosity similarly distributed, the hairs shorter, especially on the crown of the head, and the pronotal dorsum; less abundant on propodeal dorsum. Hairs of petiole, postpetiole and gaster placed exactly as in *foveolatus*.

*Type-locality.* Vision Falls, Lake Eacham National Park, N. Queensland. The type nest series was taken from a rotted log in rain forest, elevation c. 2500 ft (June 6, 1962; R. W. Taylor acc. 1399).
Additional paratype workers. Three workers from Beatrice River, Crawford's Lookout, N. Queensland (elevation probably c. 1000 ft. (Darlington, 1960: 118), rain forest, February 21-22, 1958; Darlingtons) and a single worker from Kuranda, N. Queensland (1100 ft, rain forest, July 4, 1962, R. W. Taylor acc. 1358) have the following dimensions (Crawford's Lookout material cited first): HL 0.86-0.89, 0.89 mm; HW 0.87-0.90, 0.93 mm; CI 101-102, 105; SL 0.88-0.89, 0.90 mm; SI 99-101, 97; PW 0.45-0.47, 0.47 mm; WL 0.84-0.85, 0.88 mm; Propodeal Spine L 0.27-0.28, 0.31 mm; Petiole L 0.31-0.33, 0.33 mm; Postpetiole Height 0.29-0.31, 0.31 mm. Polymorphism weak, as in P. foecolatus — SL, PW and WL negatively allometric relative to HW, HL positively allometric.

Paratype females. Two females are present in the type series, one from the holotype nest, the other from the Crawford's Lookout collection. Dimensions (Lake Eacham specimen cited first): HL 0.96, 0.95 mm; HW 1.04, 1.02 mm; CI 109, 108; SL 0.95, 0.92 mm; SI 91, 90; Scutum W 0.67, 0.65 mm; WL 1.09, 1.04 mm; Propodeal Spine L 0.32, 0.31 mm; Petiole L 0.38, 0.38 mm; Postpetiole Height 0.35, 0.35 mm; Eye Diameter 0.17, 0.17 mm; Ocular Index 16, 17. General features as in Figures 5 and 6. Pronotum without humeral spines; mesoscutum lacking parapsidal lines, propodeal spines diverging from dorsal midline at angles of 30 and 33 degrees. Mesonotal sclerites moderately coarsely longitudinally costulate, with vestiges of interstitial foveae. Pilosity as in worker; petiolar and postpetiolar hairs similarly arrayed, the petiolar peduncle with an additional pair of lateral hairs.

Color as in worker; each ocellus with an adjacent black spot; the mesosomal suture lines darkly infuscated.

Distribution and material examined. Known only from the 19 workers and two females discussed above. Lake Eacham, Crawford's Lookout and Kuranda are all at moderately high elevations on the Atherton Tableland, within the compass of the main "base-of-peninsula" rain forest system of N. Queensland.

Type deposition. Holotype, 11 paratype workers and paratype female (from holotype nest) in MCZ (Type No. 31153); four paratype workers and female in CSIRO; single paratypes in Queensland Museum, Brisbane; National Museum of Victoria, Melbourne; and British Museum (Nat. Hist.), London.

3. Pristomyrmex quadridentatus (Ern. André)
(Figs. 7-10, Plate 3)

Syntype workers. Two quadridentatus syntypes, each labeled "Sydney/Duchaussoy/TYPÉ" have kindly been loaned for study by Mlle. S. Kelner-Pillault of the Muséum National D’Histoire Naturelle, Paris. These specimens are here designated lectotype and paralectotype and are so labeled. The paralectotype gaster is missing.

Judging from subsequent records the Sydney type-locality may be outside the true range of this species and should be regarded with reservation as a distributional record until confirmed.

Dimensions as given in Table 1 (lectotype cited first). General features as in Figures 7 and 8. Mandibular dentition as in P. foveolatus. Clypeus with a median longitudinal carina, its anterior border with three separated, moderately acute denticles (apparently representing the median and outer-lateral ones of foveolatus). Antennal scrobes open posteriorly but well defined dorsally and ventrally by distinct sharp sub-parallel carinae. Occipital carina distinct. Scapes, in frontal view, laid in the scrobes, exceeding the level of the occipital border by about 1.5 × their maximum thickness. Funicular proportions as in Fig. 7. Ocular Index 17-18.

Mesosomal profile as in Figure 8. Pronotum with a distinct transverse anterior carina. Pronotal spines almost vertical, considerably stronger than propodeal ones. Mesonotum represented by a transverse carina on mesosomal dorsum. Propodeal spines each diverging from the midline at an angle of about 12 degrees; about equal in size to metapleural spines in lectotype, somewhat smaller in paralectotype. Petiole and postpetiole as in Figure 9; petiolar crest strongly arched in posterior view; postpetiole very slightly wider than petiole in dorsal view.

Head and body almost completely lacking sculpturation, smooth and strongly shining, except for a little fine shagreening on the pronotal collar and slight obscure roughening on the sides of the propodeum. Piliation generally as in P. foveolatus; petiolar and postpetiolar hairs similarly distributed, but with an additional pair on the petiolar peduncle (as in the thoracicus female). First gastric tergite completely naked. Pubescence virtually absent.

¹I have not seen the queenslandensis type, but specimens from the Mt. D’Aguilar series, listed below, have been directly compared with it for me by Dr. W. L. Brown, Jr.
Figures 7-10: *Pristomyrmex quadridentatus* André.—Lectotype worker: fig. 7, head and pronotal outline in frontal view; fig. 8, mesosoma, petiole and postpetiole in lateral view. Female (self-colored form): fig. 9, head, frontal view; fig. 10, mesosoma, petiole and postpetiole, lateral view.

Color almost even rich light-golden sienna-brown, mesosoma a shade darker, masticatory border of mandible, and segments 2-8 of antennal funiculus darkly infuscated, less dark infuscation on scape and the various carinae and spines of head and mesosoma. Eyes dark brown, almost black.

*Additional material examined, distribution.* Additional distributional records fall into two geographical clusters (Fig. 15) which coincide with the distribution of two morphological forms, apparently representing geographical variants of a single species. These variants are discussed in detail below and illustrated in plate 3; essentially there is a southern, self-colored golden-brown form (to which the lectotype and paralectotype belong), and a more northern bicolored form with dark blackish-brown mesosoma, petiole and postpetiole (equivalent to Forel’s suppressed variety *queenslandensis*). They are distributed as follows:
1. **Self-colored form**: N.E. NEW SOUTH WALES between about S. lat. 29.40 and 30.20 (not including Sydney — see above) (open circles in Fig. 15).

Specific records are: **Point Lookout to Grafton**, dealate female, April 1958, (P. F. Darlington). **New England National Park**, Platypus Creek (elevation not given, probably 2-3000 ft — see LeGay Brereton, 1963, fig. 1), in log, February 27, 1961 (Nicholls). **The Dorrigo** 3000 ft (W. Heron).

2. **Bicolored form**: Extreme S.E. QUEENSLAND, between about S. lat. 27.20 and 28.20 (closed circles in Fig. 15).

All the above records are specifically cited as rain forest collections, except the dealate female from Stradbroke Island, which has no ecological data.

**Worker variation.** Measurements and indices of workers from the above series are summarized in Table 1. The similarity of ranges and means in the two color variants is obvious and reflects their considerable resemblance in all characters except color.

The coloration of the types (Plate 3, lower figure) is typical of the self-colored form. The bicolored form has the mesosoma, petiole and postpetiole very dark blackish-brown, contrasting sharply with the golden-brown head, gaster and appendages (Plate 3, middle figure), and the antennal infuscation is much less intense. The pronotum and postpetiole may be medium to dark reddish-brown, usually in the larger specimens of a given series. Such individuals are probably incompletely colored; since these areas are the last to become fully pigmented in callow specimens.

The mesosomal spines vary in thickness, length and inclination. The pronotal pair are typically longer and thicker than the propodeal ones,

Table 1. *Pristomyrmex quadridentatus* André. Comparison of standard measurements (in mm) and indices, yielded by specimens from all known series. Mean values italicized. The types are ostensibly from Sydney (but see text). Numbers in the “series” column refer to the following localities: 1. New England National Park; 2. The Dorrigo; 3. Mt. D’Aguilar; 4. Tamborine Mt.; 5. Binna Burra.

which are usually about sub-equal to the metapleurals. The bicolored form tends to have thicker pronotal and smaller propodeal spines than the self-colored form; but the overall variation is such that the available *quadridentatus* material cannot be divided into two sets, coextensive with the color-variants, on the basis of spinational characters.
A weak negative allometric relationship between spine development and body size is evidenced; this is best marked in the bicolorated form, probably because of its better representation in the study series.

Female (previously undescribed). Six female specimens are available for study; one self-colored, five bicolorated.

1. Self-colored form. A single dealate labeled Point Lookout—Grafton, N.S.W., has the following dimensions: HL 1.05 mm; HW 1.07 mm; CI 102; SL 0.98 mm; SI 88; Scutum W 0.68 mm; WL 1.20 mm; Propodeal Spine L 0.22 mm; Petiole L 0.35 mm; Postpetiole Height 0.39 mm; Eye Diameter 0.22 mm; Ocular Index 21. General features as in Figures 9 and 10. Pronotum with a partly broken fine, arched transverse carina, its humeri each with a low obtuse tubercle. Parapsidal lines of mesoscutum very obscure, essentially vestigial. Bases of propodeal spines connected by a transverse carina. Metapleural spines slightly longer and more acute than propodeal ones.

Color and pilosity as in worker, the ocelli each with an adjacent small dark brown spot, the mesosomal suture lines and axillary sclerites infuscated dark brown.

2. Bicolorated form. Two dealate specimens from Mt. D'Aguilar Range, one each from Stradbroke Island and Tamborine Mt., and an aleate from Binna Burra, have the following dimensions: HL 0.95-1.22 mm; HW 0.99-1.30 mm; CI 102-106; SL 0.94-1.18 mm; SI 91-95; Scutum W 0.62-0.85 mm; WL 1.10-1.42 mm; Petiole L 0.32-0.46 mm; Postpetiole Height 0.32-0.43 mm; Eye Diameter 0.19-0.26 mm; Ocular Index 19-20. The smallest specimen is from Mt. D'Aguilar Range, the largest is the Binna Burra aleate (which has a forewing length of 1.9 mm, hindwing length of 1.3 mm). Distribution of indices in the series implies negative allometry of scape length and head length, relative to head width. Pronotal spine development variable, apparently negatively allometric, smallest specimen with a low obtuse tubercle, largest one with an almost imperceptible slightly raised convexity. Propodeal spines similarly variable, best developed in smallest individuals (about comparable to self-colored specimen), represented only by slightly raised propodeal corners in largest specimen. Characters otherwise as in self-colored form, with the scapes proportionately slightly longer.

Coloration as in worker, ocellar area darkly infuscated; pronotum and scutum reddish brown in the Binna Burra aleate, which may be incompletely colored.

Ecology. All detailed records of quadridentatus show that nests are usually located in rotting logs, a fact confirmed in the field by
the author, and by the experienced Australian collector B. B. Lowery, S. J., (pers. comm.).

On May 21-23, 1962, I established that the bicolored form is probably an exclusively nocturnal forager. During 4 days of intensive collecting in rain forest near Binna Burra, workers were never encountered abroad from nests during the day. At night, however, 22 workers in seven samples were taken as strays, during about four hours total collecting. These specimens were all collected between two and six hours after sunset (the limits of the observation period), and all were in the open on the surfaces of widely separated rotting logs. Several further individuals were taken near the ground on tree trunks, and one was collected from foliage in a sweep-net. In several cases these individuals appeared to be following trails, but they were always well separated from each other, at distances of 14-20 cm. The ants moved slowly, their rate of progress being estimated at 10-15 cm per minute. The nature of the food was not determined.

Relationships. See discussion on p. 35.

4. **Pristomyrmex wheeleri** new species
   (Figs. 11-15, Plate 3)

*Type workers.* The following description is based on the holotype and numerous paratypes from all parts of the distributional range given below.

Dimensions (holotype cited first): HL 1.14, 0.97-1.23 mm; HW 1.26, 1.04-1.40 mm; CI 111, 108-116; SL 1.11, 0.92-1.14 mm; SI 88, 81-90; PW 0.60, 0.51-0.67 mm; WL 1.09, 0.89-1.20 mm; Pronotal Spine L 0.17, 0.15-0.20 mm; Propodeal Spine L 0.35, 0.27-0.39 mm; Petiole L 0.41, 0.36-0.44 mm; Postpetiole Height 0.38, 0.31-0.43 mm. General features as in Figures 11 and 12, and Plate 3 (upper figure). Similar to *P. quadridens*, as described above, but differing in the following features:

1. Generally larger size (HW 1.04-1.40 mm, opposed to 0.88-1.14 mm in *quadridens*), with much broader head (CI 108-116 against 97-103), and lower Scape Index (81-90 opposed to 93-105).

2. Inferior carina of antennal scrobe vestigial or absent.

3. Pronotal and propodeal spines longer and more slender, in side view approximately sub-equal in length; metapleural spines acute, rarely more than half as long as propodeals.

4. Pilosity similar, the body hairs thicker and longer, petiolar peduncle with a single hair on each side, first gastric tergite naked.

5. Color distinctive; head deep dark amber-brown. Mandibles, clypeus and antennae rich golden-brown. Remainder of body golden-brown, much like the self-colored form of *quadridens*, but more
Figures 11-14: *Pristomyrmex wheeleri* n. sp. — Holotype worker: fig. 11, head and pronotal dorsum, frontal view; fig. 12, mesosoma, petiole and postpetiole, lateral view.—Paratype female: fig. 13, head, frontal view; fig. 14, mesosoma etc., lateral view.

yellowish. Posterior half of first gastric tergite shaded medium to dark reddish brown.

*Type locality.* Vicinity of Binna Burra, S.E. Queensland. The type colony was taken in soil under a stone in rain forest, elevation c. 2800 ft (May 24, 1962, R. W. Taylor acc. 1281).

*Worker variation.* Negative allometry of head length and scape length, relative to head width, is suggested by the distribution of cephalic and scape indices in the study series. Other characters, including the clypeal structure and the development of the mesosomal spines, show no apparently significant variation.

*Paratype females.* A female from the type-nest (cited first), and six others, one from each locality given below except National Park and Woodenbong, have the following dimensions: HL 1.11, 1.17-1.25 mm; HW 1.23, 1.31-1.42 mm; CI 112, 112-114; SL 1.04,
Figure 15 (above): Distribution of members of the *Pristomyrmex quadridenatus* group. Land above 200 meters elevation shaded.

EXPLANATION OF PLATE 3 (opposite)

Workers of the *Pristomyrmex quadridenatus* group, to illustrate coloration. Top: *P. wheeleri* n. sp., from Binna Burra, S. E. Queensland. Middle: *P. quadridenatus* André, bicolored form, from Binna Burra (sympatric with *wheeleri*). Bottom: *P. quadridenatus* André, self-colored form, from New England National Park (Point Lookout) (allopatric with *wheeleri*). Author del.
1.08-1.12 mm; SL 85, 79-82; Scutum W 0.67, 0.78-0.84 mm; WL 1.19, 1.26-1.36 mm; Propodeal Spine L 0.33, 0.35-0.39 mm; Petiole L 0.41, 0.44-0.48 mm; Postpetiole Height 0.39, 0.41-0.45 mm; Eye Diameter 0.24, 0.26-0.27 mm; Ocular Index 20, 19-20. Negative allometry of scape length and head length, relative to head width, is indicated. General features as in Figures 13 and 14. Distinguished from _P. quadridentatus_ by very different proportions and coloration. Structure of clypeal apron variable, usually as in Figure 13; the median projection narrowed with reduced teeth in one specimen, bidentate in another, and completely edentate in a third. Transverse pronotal carina distinct. Pronotal spines variable, ranging from low rounded tubercles to small acute teeth (maximally about 0.03 mm long), with no apparent allometric tendency. Parapsidal lines feeble to moderately distinct. Propodeal spines almost invariable, their bases bridged by a low carina. Metapleural spines acute, distinctly shorter than propodeals.

Color and pilosity as in worker, mesosomal suture lines and alary sclerites infuscated dark brown.

_Type deposition._ Holotype and numerous paratypes (worker and female) in MCZ (Type No. 31154), paratypes in CSIRO; Queensland Museum, Brisbane; Australian Museum, Sydney; National Museum of Victoria, Melbourne, and other Australian collections, also British Museum (NH), London, and B. P. Bishop Museum, Honolulu.

_Ecology._ All the above records are from rain forest. Sixteen of the
18 colonies listed were found in soil under or between stones, one was in a rotting log (RWT acc. 819), and one in a rotting wood fragment (RWT acc. 721). Nesting behavior thus contrasts with that of the sympatric bicolored form of *quadridentatus*, which has been found nesting only in rotting logs. Lowery’s six Cunningham’s Gap colonies each contained 18 to 36 workers and one queen. At Binna Burra I searched extensively for foragers of *wheeleri* but encountered only one (acc. 1210), which was taken two hours after sunset on top of a small rock, later found to shelter a colony. Foraging behavior presumably is unlike that of *P. quadridentatus* (see p. 48).

**Relationships.** See below.

**Distribution and Variation in the Quadridentatus Group**

All known bicolored series of *Pristomyrmex quadridentatus* were collected in immediate geographical and temporal sympatric association with *P. wheeleri*, while the self-colored form has never been taken in such association. This corollation invites the hypothesis that character displacement of *quadridentatus* has occurred wherever the species is sympatric with *wheeleri*.

Character displacement is the situation, usually involving several related species, where interspecific differences are more distinct in areas of sympathy than in areas of allopatry. This phenomenon has long been recognized, but was first crystallized by Brown and Wilson (1956), who reported its occurrence in birds, frogs, fishes, crabs and various insects. Subsequent reports involve many animal groups, including the South African cyprinid fishes, *Barbus marequensis* and *B. natalensis* (Farquharson, 1962), the North American salamanders *Plethodon cinereus* (Green) and *P. richmondi* Netting and Mittleman (Highton, 1962), the Central American iguanids *Basiliscus plumifrons* Cope and *B. vittatus* Weigmann (Maturana, 1962), the East African gekkonids *Holodactylus africanus* Boettger and *H. cornii* Scortecci (Laurent, 1964), several pairs of Indian nuthatches of the genus *Sitta* (Ripley, 1959) and the New Zealand pelecypods *Bassinia yatei* (Gray) and *B. parva* Marwick, which apparently underwent displacement on becoming sympatric in the Lower Pleistocene (Fleming, 1959). Few of these cases have been studied in detail aimed at elucidating the selective significance of the displacement, though it seems clear that secondary reinforcement of premating isolating mechanisms, or special adaptation to greater niche specificity resulting from competitive displacement, are involved in some cases.

This hypothesis is invoked to explain the origin of the bicolored form of *P. quadridentatus* on limited distributional evidence, which needs supplementation. A selective mechanism is difficult to envisage since there is no evidence that color is involved in interspecific relations
between these ants. Ecological differences between the sympatric forms are reported above; at Binna Burra *quadridentatus* nests in logs and forages openly at night, while *wheeleri* nests under stones and apparently forages cryptically. Nothing is known of the behavior of self-colored *quadridentatus* and such information is required. Bicolored *quadridentatus* and *wheeleri* are perhaps the most spectacularly colored members of their genus; their coincident distribution suggests that the causal factors producing their color patterns may be inter-related. The two "forms" of *quadridentatus* might prove ultimately to be good biological species, but even if this is the case, character displacement need not be rejected in explaining their color differences. These ants are worthy of much further study.
